ABSTRACT

A novel technique to bond polymer substrates using PDMS-interface bonding is presented in this paper. This novel bonding technique is promising to achieve precise, well-controlled, low temperature bonding of micro fluidic channels. A thin (10-25 μ m) Poly(dimethylsiloxane) (PDMS) intermediate layer was used to bond two polymer (PMMA) substrates without distorting them. Micro channel patterns were compressed on a PMMA substrate by hot embossing technique first. Then, PDMS was spin-coated on another PMMA bare substrate and cured in two stages. In the first stage, it was pre-cured at room temperature for 20 hours to evaporate the solvents. Subsequently, it was bonded to the hot embossed PMMA substrate. In the second stage, PDMS was completely cured at 90°C for 3 hours and the bonding was successfully achieved at this relatively low temperature. Tensile bonding tests showed that the bonding strength was about 0.015MPa. Micro fluidic channels with dimensions of 1mmx2cmx1mm were successfully fabricated using this novel bonding method.

Keywords: PMMA, PDMS, Hot Embossing

1. INTRODUCTION

In recent years, polymer-based micro fluidic devices have become increasingly important in biological applications (e.g., see [1]). However, polymer substrates must be bonded to make functional micro channels and the adhesion between the substrates is a problem of great practical concern. Existing polymer-to-polymer substrate bonding methods include thermal-compression, ultrasonic, and gluing by application of either epoxy or methanol. Unfortunately, these techniques are not precise when compared to standard IC/MEMS bonding processes, i.e., they may induce global and localized geometric deformation of the substrates or leave an interfacial layer with significant thickness variation. For channels in the range from millimeter to a few hundred microns, these drawbacks are tolerable. However, it is implausible to construct micron and nanometer sized channels using these techniques since significant global and local material deformations may distort the micro/nano channel geometries. We have recently presented our work in using localized microwave heating to bond polymer (e.g., PMMA) substrates with a uniform interface layer about 1 μ m without causing any global deformations [2]. The operation of microwave bonding is convenient and well-controlled. However, microwave bonding can only be applied to a relatively small surface area between two bonding substrates, e.g., 1cmx1cm.

Polymer is the most common adhesive bonding material for micro fluidic devices because the bonding temperature is relatively low. Benzocyclobutene (BCB) [3] and Teflon-like amorphous fluorocarbon polymer [4] are used as the adhesive layers to bond different materials such as silicon and glass. However, their required bonding temperature is still over 100°C. SU-8 is another polymer that requires bonding temperature of ~95°C [5]. For glass and silicon substrates bonding, bonding temperature over 100°C is still acceptable; but for polymer substrates, this would greatly affect the

bonding performance. For example, the glass transition temperature of PMMA is only 105°C, hence, bonding temperature that is over 100°C cannot be applied to PMMA-to-PMMA bonding as it would melt the channel patterns on PMMA substrate.

PDMS, an elastomeric polymer, which is biocompatible, transparent, permeable to gases and low cost, is becoming more popular among the micro fluidic device community. Replica molding technique is commonly used to fabricate PDMS micro fluidic devices [6]. The preparation process of PDMS is also simple. In addition, its low curing temperature (<100°C) makes it an excellent material for bonding polymer substrates since many polymer substrates cannot withstand a high bonding temperature (>200°C). Currently, PDMS is widely used as the structural material for micro fluidic devices because of its biocompatibility and low cost properties. 3-D micro channels can be made easily and rapidly by replica molding method. Typically, 3-D channels are formed by exposing both PDMS layers to oxygen plasma and then bond them immediately after the plasma treatment [6]. PDMS can be irreversibly adhered to a number of materials such as glass, silicon and quartz [7]. However, PDMS cannot be adhered to PMMA by this method. Instead of using the oxygen plasma treatment, we have developed a novel bonding method, which used spin-coated PDMS as the interface to bond two PMMA substrates during the curing of PDMS. This method is effective, low cost, fast, and simple to fabricate micro channels.

In this paper, we will present our recent progress in bonding PMMA substrates with large surface area (4cmx4cm) at low temperature using a thin spin-coated PDMS layer (10-25µm) as the intermediate layer. We found that PDMS could be made to adhere well to PMMA during the curing process of PDMS and no global deformation was generated in the substrates. We have fabricated a closed micro channel using this method. In our experimental results, the bonding strength was 0.015MPa and no leakage occurred inside the channel.

2. FABRICATION OF MICRO FLUIDIC CHANNEL

2.1 Micro patterning of PMMA by hot embossing technique

Micro channels on PMMA were created by using the hot embossing technique similar to the one reported in [8]. The fabrication process used in our group is illustrated in Figure 1. A layer of silver was deposited on silicon substrate. SU-8 was then patterned on silver by lithography. Next, nickel was deposited on the SU-8 mold by electroplating to make a metal mold. Nickel was used as the material of the metal mold because it is much harder than PMMA (Young's modulus=200GPa). The metal mold was then released and inserted into the hot embossing machine. The hot embossing machine used in our lab and its components are shown in Figure 2. The PMMA substrate was first heated to 120°C, which was slightly above the glass transition temperature of PMMA ($T_g=105^\circ\text{C}$). Then a pressure of 6.89MPa was applied by a hydraulic press to compress the mold towards the PMMA substrate, as shown in Figure 1c, which allowed the channel pattern on the metal mold to be transferred to the PMMA substrate. The substrate and the mold were then cooled and separated.

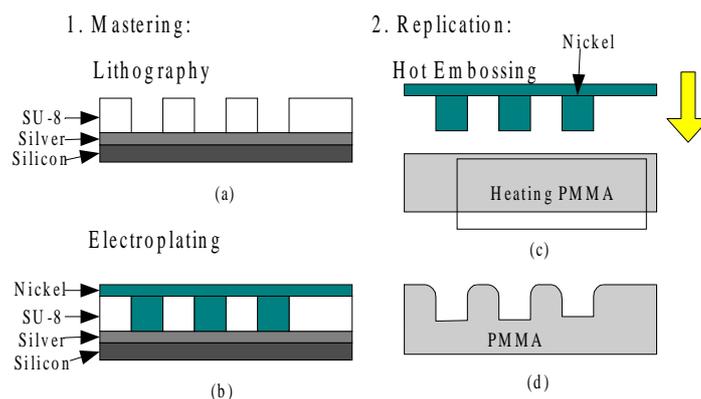

Figure 1. Illustration of the hot-embossing process. Two main procedures: Mastering and replication. (a) SU-8 was patterned on silver by lithography. (b) Nickel was electroplated on the SU-8 mold to make the metal mold. (c) Nickel mold was released and compressed on the heated PMMA substrate. (d) Channel pattern on the nickel mold was transferred to the PMMA substrate.

2.2 Formation of micro channel by bonding process

The fabrication process of micro channel on PMMA is illustrated in Figure 3. PDMS prepolymer (SYLGARD 184 Silicone Elastomer Kit, Dow Corning) was mixed with its curing agent in the volume ratio of 10:1. Then the prepolymer mixture was degassed in a desiccator with a vacuum pump at 50 torr for half an hour to remove any bubbles created during mixing. A 10-50 μ m PDMS prepolymer mixture was spun on the bare PMMA surface. The size of the PMMA substrates was 4cm wide, 4cm long and 0.2cm thick. After spinning on the PDMS, the substrate was pre-cured at room temperature first for about 20 hours to evaporate most of the solvents. The thickness of PDMS was controlled by the spinning rate as shown in Figure 4. The two substrates were not bonded immediately because air could be trapped and bubbles could appear in PDMS layer. However, The PDMS layer was only partially cured after 20 hours. 24 hours is needed to fully cure PDMS at room temperature. This partially cured PDMS was very viscous and sticky, and was suitable for bonding. An example of two PMMA substrates successfully bonded is shown in Figure 5. The bonded substrates were heated at 90°C for 3 hours under a pressure of 50kPa. PDMS was thus completely cured and the channel was sealed.

3. EXPERIMENTAL RESULTS

3.1 SEM examination

The bonded sample was cut by a diamond saw and the bonding quality of the micro channel was examined. SEM pictures of the cross section of the PMMA-PDMS-PMMA interface are shown in Figure 6. In this figure, we found that the interfacial layer was precise and well-controlled. The thickness was approximately 50μm. PDMS at plain areas, as shown in Figure 6a, adheres well to both PMMA substrates. However, in Figure 6b, we found that PDMS was squeezed to the round edges of the channel. The round edges of the channel were created by the hot embossing process. As shown in Figure 7, the channel walls were curved due to the contact-stress between the mold and PMMA as we have shown in [9]. Nevertheless, no PDMS was squeezed into the channel to block it.

3.2 Tensile bonding test

The bonding strength test was performed by using QTest™ of MTS Systems Corporation. The test set up is shown in Figure 8a. In order to fit the sample to the gripper of the machine, a piece of PMMA attachment substrate was adhered to both the top and bottom surfaces of the sample as shown in Figure 8b. Chloroform was used to attach this attachment substrate to the samples. The evaluation results with various parameters are listed in Table 1. The bonding strength was about 0.015 MPa. The results show that the thickness of the interfacial layer does not greatly affect the bonding strength. However, it does affect the bond quality. Fewer bubbles formed with a thinner PDMS layer. Besides the thickness of PDMS layer, the pre-curing time of PDMS at room temperature also has a significant influence on the bonding quality. Sufficient pre-curing time (~20 hours) is needed to reduce bubble formation and achieves a larger bonded area. A larger bonded area leads to a stronger bonding strength.

Table 1. Evaluation results of the bonding tests.

Sample No.	PDMS thickness (μm)	Curing time at room temperature (hr)	Bonding temperature ($^{\circ}\text{C}$)	Bonding time (hr)	Bonding strength (MPa)	Bonded area (%)	Bubbles formed
1	10	20	90	3	0.015689	100	No
2	25	20	90	3	0.015389	95	Yes
3	35	20	90	3	0.014711	95	Yes
4	10	6	90	1.5	0.011922	90	Yes
5	25	6	90	1.5	0.009900	85	Yes

3.3 Leakage test

The most common concern about micro fluidic system is the leakage problem. Many existing polymer-to-polymer substrate bonding methods such as gluing by epoxy or methanol suffered from uneven bonding and leakage near the edge of the device. Therefore, the fabricated channels were tested for leakage. Since both PMMA and PDMS are transparent, it is difficult to examine the bonding quality by human eyes. Color dye was injected into a channel by a needle, and no leakage occurred in the channel as shown in Figure 9a. Two different color dyes were injected into the mixing channel as shown in Figure 9b. The dyes were mixed in the large channel. The channel dimensions are $w=1\text{mm}$, $h=1\text{mm}$, with a total length of 2cm.

4. DISCUSSION

4.1 Treatment of PDMS by oxygen plasma

Besides the bonding method we described above, we have tried another method to bond PMMA substrates together. Oxygen plasma treatment is commonly used to bond PDMS. It is reported that the bond between PDMS and glass using oxygen plasma can withstand a pressure of 0.2-0.3MPa [8]. We tried spinning on PDMS on both bare and embossed PMMA and cured separately. For the embossed substrate, PDMS was spun on first before compressing the channel on it. PDMS was cured during the heating of the hot embossing process. The two substrates were treated with oxygen plasma with the conditions of 70W, 40Pa, and 30s. The two substrates were bonded immediately. After a few minutes, the sample was examined. We found that the two substrates were not adhered well. It was caused by the non-uniformity of the PMMA surface and there was a gap between the two substrates. The contact surface area of the two PDMS layers was small. Therefore, only a weak adhesion force was produced.

4.2 Irreversible adhesion of PDMS and PMMA

Due to their chemical compositions, PDMS cannot adhere to PMMA irreversibly using oxygen plasma treatment. They can only make van der Waals contact with each other. However, we have found that by decreasing the mixing ratio

between the prepolymer and the curing agent of PDMS and increasing its curing temperature, PDMS can adhere to PMMA substrate irreversibly. The mixing ratio of PDMS was decreased to 3:1. The spin-coated PDMS was cured at 170°C for 3 hours. However, this method cannot apply to PMMA-PDMS-PMMA bonding because the required bonding temperature is above the glass transition temperature of PMMA ($T_g=105^\circ\text{C}$), i.e., the channel patterns will be melted at this high bonding temperature. This method can apply to other materials such as glass and silicon to PMMA bond. The fabrication process is illustrated in Figure 10. The channel was first made by replica molding. SU-8 was used to make the mold master. The PDMS was peeled off after curing at 90°C for 3 hours. The PDMS channel was adhered to glass using oxygen plasma treatment. PDMS was spun on a bare PMMA substrate and cured at 170°C for 3 hours to make an irreversible adhesion. The two substrates were bonded together by oxygen plasma treatment to make a closed channel.

5. CONCLUSIONS

A low temperature bonding technique for polymer-based substrates to achieve a precise and well-controlled bonding interfacial layer has been presented. The bonding technique, using spin-coated PDMS, shows a low bonding temperature ($\sim 90^\circ\text{C}$) and bonding strength of 0.015 MPa in PMMA-PDMS-PMMA interface. The PMMA substrates were bonded without any global geometric deformation. The bonded substrates were tested with tensile bonding test and leakage test. Results of tensile bonding test showed that thickness of the interfacial layer and pre-curing time of PDMS at room temperature were critical for realizing good bonding quality. Color dyes were injected into a closed channel to show that no leakage occurred. We have demonstrated an effective, low cost, fast and simple way to fabricate polymer micro channels at relatively low temperatures.
